Left heart failure, a challenging diagnosis in cardiology

Insuficiência cardíaca esquerda, um desafio diagnóstico em cardiology

Patent ductus arteriosus (PDA) is one of the most common congenital heart defects, and causes left ventricular volume overload. However, it is a rare finding among adults due to the lack of symptoms related to its small size, and it is not usually associated with other congenital lesions.

A 53-year-old woman was referred for percutaneous closure of a PDA. She had undergone a secundum atrial septal defect (ASD) closure in 2007, detected after a cryptogenic stroke. After this procedure, her clinical history was remarkable for fatigue, dyspnea and orthopnea with New York Heart Association (NYHA) functional class III, and a continuous murmur was heard over the left sternal border. A routine transthoracic echocardiogram performed in 2013 revealed a continuous flow from the aorta towards the pulmonary artery, with left-sided chamber dilation (ejection fraction 50%) and normal pulmonary artery pressure. The device previously implanted at the atrial septum was correctly positioned and without residual shunt (Figure 1). The PDA was closed by placing an Amplatzer\textsuperscript{TM} Duct Occluder guided by fluoroscopy and intracardiac echocardiography (Figure 2). The procedure was uneventful. The 12-month follow-up showed significant clinical improvement (NYHA functional class II), no residual shunt, and normal left chamber dimensions (Figure 3).

In this case, the association with an ASD may have delayed the clinical manifestations of the PDA, as the previous left-to-right shunt probably compensated for the left ventricular volume overload. It is crucial to perform a complete high-quality echocardiogram in such patients with congenital heart disease, in order to screen for associated anomalies.
