Case report

Coronary fistulas are rare malformations with an estimated incidence of <1% in angiographic studies. They are usually diagnosed as incidental findings on coronary angiography. Detection by echocardiography is rarely reported; the most frequent finding is right chamber dilatation, as in most cases the fistula drains directly into the right heart.

A 66-year-old woman with permanent atrial fibrillation was admitted for fatigue on moderate exertion. On physical examination, a systolic-diastolic murmur was detected at the left sternal border. She had previously undergone

Figure 1   Angiographic image of the fistula (yellow arrow) arising from the proximal segment of the anterior descending artery and draining into the pulmonary artery. Left: right oblique cranial view; right: lateral view.
Further echocardiographic assessment in parasternal view documented dilatation of the pulmonary artery trunk (34 mm) and normal-sized right chambers. Doppler echocardiography identified continuous laminar flow, mainly in diastole, peak velocity 0.1 m/s (Figure 2), corresponding to the site of coronary fistula drainage. Areas of turbulent flow were seen along the course of the anterior descending artery, corresponding to branching of the fistula at this point (Figure 3). Pulmonary artery pressure was estimated at 28 mmHg. No other congenital defects were detected.

Since the patient was symptomatic, it was decided to perform percutaneous closure, but this was unsuccessful and she subsequently underwent surgical ligation of the fistula.
