Abstract

Introduction: Biomarkers in dilated cardiomyopathy (DCM) reflect various pathobiological processes, including neurohormonal activation, oxidative stress, matrix remodeling, myocyte injury and myocyte stretch. We assessed the role of biomarkers in clinical and echocardiographic parameters and in left ventricular (LV) reverse remodeling (LVRr).

Methods: In this prospective study of 50 DCM patients (28 men, aged 59±10 years) with LV ejection fraction (LVEF) <40%, LVRr was defined as an increase of >10 U in LVEF after optimal medical therapy.

Results: Baseline LVEF was 25.4±9.8% and LV end-diastolic diameter (LVEDD)/body surface area (BSA) was 34.2±4.5 mm/m². LVRr occurred in 34% of patients within 17.6±15.6 months. No correlation was found between B-type natriuretic peptide (BNP), 25-hydroxyvitamin D (25(OH)D), CA-125, high-sensitivity C-reactive protein (hs-CRP), lipoprotein(a) [Lp(a)], noradrenaline, adrenaline, renin or aldosterone and LVRr. Patients in NYHA class III or IV, with pulmonary congestion or ankle edema, had higher CA-125, cystatin C, BNP and hs-CRP levels (p<0.05). CA-125 was correlated with BNP (r=0.61), hs-CRP (r=0.56) and uric acid (r=0.52) (all p<0.01). BNP correlated directly with LVEDD (r=0.49), LV volumes (r=0.51), pulmonary artery systolic pressure (PASP) (r=0.43) and E/e’ (r=0.31), and was inversely correlated with LVEF (r=-0.50) and e’ velocity (r=-0.32) (p<0.05). CA-125 was positively correlated with left atrial volume/BSA (r=0.46), E/A ratio (r=0.60) and PASP (r=0.49) (p<0.05).

**Conclusions:** No correlation was found between biomarkers and LVRR, but CA-125, BNP and hs-CRP were predictors of clinical severity and congestion. BNP correlated with parameters of systolic and diastolic dysfunction, while CA-125 correlated with measures of diastolic dysfunction.

**O papel dos biomarcadores na miocardiopatia dilatada – avaliação de gravidade clínica e remodelagem reversa**

**Resumo**

**Introdução:** Os biomarcadores na miocardiopatia dilatada (DCM) refletem vários processos fisiopatológicos: ativação neuro-hormonal, stress, remodelagem da matriz extracelular, lesão e estiramento miocitários. Procuramos associar biomarcadores com parâmetros clínicos, ecocardiográficos e com a reversão da remodelagem do ventrículo esquerdo (LVRR).

**Métodos:** Estudo prospectivo de 50 doentes com DCM (28 homens, idade 59±10 anos) com fração de ejeção ventricular esquerda (LVEF) <40%. A LVRR definIU-se como aumento >10 U da LVEF, após a terapêutica médica otimizada.

**Resultados:** A LVEF basal foi de 25,4±9,8% e o diâmetro do VE (LVD)/BSA de 34,2±4,5 mm/m². A LVRR ocorreu em 34%, em 17,6±15,6 meses. Não houve correlação entre BNP, 25-OH-vit D, CA 125, hsCRP, Lp(a), noradrenalina, renina, aldosterone e LVRR. Doentes em classe NYHA (III-IV), com congestão pulmonar ou edema periférico apresentaram níveis mais elevados de CA 125, cistatina C, BNP e hsCRP (p<0,05). O CA 125 correlacionou-se com níveis de BNP (r=0,61), hsCRP (r=0,56) e ácido úrico (r=0,52) (p<0,01). O BNP relacionou-se diretamente com LVD (r=0,49), volume VE (r=0,51), PSAP (r=0,43), razão E/e′ (r=0,31); e inversamente com LVFF (r=0,50) e vel. e′ (r=0,32) (p<0,05). O CA 125 correlacionou-se com o volume AE/BSA (r=0,46), razão E/A (r=0,60) e PSAP (r=0,49) (p<0,05).

**Conclusões:** Não houve correlação entre biomarcadores e LVRR, contudo, o CA125, BNP e hsCRP foram preditores de gravidade clínica e de congestão. O BNP relacionou-se com parâmetros de disfunção sistólica e diastólica, enquanto o CA 125 se relacionou com medidas de disfunção diastólica.

**Introduction**

Heart failure (HF) is a major public health burden and is often a clinically silent process, with progressive cardiac remodeling that eventually leads to symptomatic presentation late in the course of disease progression. The severity and prognosis of HF vary substantially, ranging from mild disease that is easily managed with neurohormonal blockade to advanced illness requiring mechanical support or heart transplantation.¹ Physicians use biomarkers as additional tools to aid clinical diagnosis and treatment and to identify high-risk subjects.²

The progression of HF is complex and is driven by multiple biological processes, including inflammation, oxidative stress, neurohormonal activation, vascular remodeling, myocyte injury, and renal impairment.³ Current guidelines recommend testing B-type natriuretic peptide (BNP) or N-terminal pro-BNP (NT-proBNP).⁴

The progression of HF is associated with left ventricular (LV) remodeling, which manifests as gradual increases in LV end-diastolic and end-systolic volumes, wall thinning, and a change in chamber geometry to a more spherical, less elliptical shape, with a continuous decrease in LV ejection fraction (LVEF).⁵ When ventricular remodeling is advanced, it is self-sustaining, leading to disease progression, regardless of neurohormonal status.

However, in some situations, there may be LV reverse remodeling (LVRR), characterized by decreases in LV dimensions, normalization of LV shape and improvement of systolic function.

In this work, we set out to find associations between biomarkers and clinical severity and echocardiographic parameters. We also sought predictors of LVRR after optimal pharmacological therapy. We used available biomarkers that reflect diverse biological pathways in HF: adrenaline, noradrenaline, plasma renin, aldosterone and BNP (neurohormonal activation), high-sensitivity C-reactive protein (hs-CRP), cancer antigen CA-125 (inflammation), uric acid and lipoprotein(a) [Lp(a)] (oxidative stress), creatinine and cystatin C (renal function), and 25-hydroxyvitamin D
Biomarkers in dilated cardiomyopathy

[25(OH)D] (extracellular remodeling), in a cohort of HF out-
patients.

Methods

We included consecutive adult patients with dilated car-
diomyopathy (DCM) followed in an HF outpatient clinic in
a tertiary care center, diagnosed less than 24 months previ-
ously and with two values of LVEF of <40% more than one year
apart. This is a biomarker substudy of a previously published
work by the same authors. In this new cohort we excluded
patients with atrial fibrillation, in order to avoid measure-
ment errors in the assessment of LVEF. We also excluded
DCM patients with secondary etiologies including ischemic,
valvular, inflammatory and toxic cardiomyopathy.

At baseline, patients underwent clinical assessment of
symptoms and signs of HF. Peripheral congestion (ankle
edema) and pulmonary congestion were assessed, the latter
by lung auscultation and chest X-ray. All patients underwent
electrocardiogram (EGC) and transthoracic echocardiog-
gram and blood laboratory tests. Patients were managed
according to current clinical practice guidelines and efforts
were made to reach the recommended target doses for all
therapies. During follow-up, periodic clinical assessment,
laboratory tests and echocardiography were performed
three and six months. All patients gave their written
informed consent. This study was performed in accordance
with the recommendations of the Declaration of Helsinki
and approved by the hospital’s ethics committee.

Definition of left ventricular reverse remodeling

LVRR was assessed once optimal medical therapy was
reached and was defined as the occurrence in two sub-
sequent echocardiograms, more than six months apart, of
an absolute increase of 10 units of LVEF, together with
a decrease in LV end-diastolic diameter (LVEDD), without
worsening of mitral regurgitation, if present, in the absence
of cardiac resynchronization therapy (CRT) or mechani-
cal ventricular assistance. Patients who received CRT were
considered not to have LVRR, so only echocardiographic
parameters measured before implantation of a CRT device
were considered in the analysis.

Transthoracic echocardiography protocol

Transthoracic echocardiography was performed at baseline
and during follow-up using a commercially available echo-
cardiographic system (General Electric Vivid 7.0) with a 2.5
MHz transducer.

Chamber quantification parameters were measured
according to the standards defined by the American Soci-
ety of Echocardiography and the European Association
of Echocardiography. LVEF was calculated by Simpson’s
biplane method; mitral and tricuspid regurgitation was mea-
sured by Doppler, scored on a scale from 0 to 4; and
pulmonary artery systolic pressure (PASP) was calculated
from tricuspid velocities. LV mass was calculated using the
formula proposed by Devereux et al. The LV sphericity
index was calculated as the ratio of dimensions in long-axis
and short-axis views. Early diastolic (E) and atrial (A) wave
velocities, E/A ratio, and E-wave deceleration time were
measured using pulsed wave Doppler recording from api-
cal 4-chamber view. Spectral pulsed-wave Doppler-derived
early diastolic velocity (e’) was obtained from the septal
mitral annulus, and the E/e’ ratio was calculated to obtain
an estimate of LV filling pressure.

All data were stored digitally, and off-line data analy-
sis was performed. To assess variability in interpretation,
each echocardiograms were analyzed independently by two
specialists in echocardiography, blinded to the study. Repro-
ducibility of the measurements was calculated on the basis
of standard error of the estimate; both inter- and intra-
observer variation were ≤5% for follow-up LVEF.

Biomarker assessment

All biomarkers were measured from plasma obtained at the
time of study entry.

Blood samples were collected after a 30-min rest
through a venous catheter and the first sample was
rejected. Plasma catecholamines were determined by
high-performance liquid chromatography (Gilson). BNP was
measured by chemiluminescent immunoassay (Abbott).
Plasma renin activity and aldosterone was determined by
radioimmunoassay. hs-CRP was measured by nephelometry
(Vista, Siemens). CA-125 and 25(OH)D were determined by
chemiluminescence (Abbott and Roche, respectively).

Statistical analysis

All values are reported as mean ± SD, median ± interquar-
tile range, or percentages, according to the characteristics
of the data. Differences between subjects in each arm were
assessed using the chi-square test for categorical variables
and the Student’s t test or Mann-Whitney test for continuous
variables, as appropriate. A two-tailed p <0.05 was consid-
ered to indicate statistical significance.

A paired Student’s t test was used to assess changes
from baseline. The relationships between biomarkers and
echocardiography parameters were analyzed by Spearman’s
correlation test. Data were analyzed using the SPSS 23.0
statistical package (IBM SPSS Inc., Chicago, IL, USA).

Results

We studied 50 patients, 28 men (56%), aged 59±10 years
and followed for 39±22 months. The majority of patients
(62%) were in New York Heart Association (NYHA) class II.
At baseline, mean LVEF was 25.4±9.8%, LVEDD was 62.4±7.4
mm, LVEDD/body surface area (BSA) was 34.2±4.5 mm/m²
and grade >II/IV mitral regurgitation was present in 34% of
patients. Table 1 details the patients’ baseline characteris-
tics.

On the ECG, 66% had left bundle branch block (LBBB), 22%
had LV hypertrophy criteria and all were in sinus rhythm.

At the beginning of the study, 76% of patients were
being treated with angiotensin-converting enzyme inhibitors
(ACEIs)/angiotensin receptor blockers (ARBs), 62% with
beta-blockers and 14% with aldosterone receptor antagonists (Table 1).

At the end of follow-up, 94% of the patients were being treated with ACEIs/ARBs, 98% with beta-blockers and 60% with aldosterone antagonists. Optimal recommended doses of ACEIs/ARBs were reached in 42% and optimal doses of beta-blockers were reached in 48%. Only 4% needed urgent transplantation or died (two deaths), 22% were hospitalized for worsening HF and 40% received an implantable cardioverter-defibrillator (ICD). At the end of follow-up only 15 patients had LBBB and LVEF ≤35%. Four (8%) received a cardiac resynchronization therapy device (CRT-D); the others did not receive a CRT-D because of NYHA class I, technical problems, patient refusal, transient LVEF recovery, presence of LV diverticulum or old age.

Prevalence and prognostic value of left ventricular reverse remodeling

LVRR occurred in 34% of patients within 17.6±15.6 months (mean time to first echocardiogram to show LV recovery). Patients with LVRR had a final LVEF of 48.9±7.9% (∆LVEF of 22.4%), and had a significant decrease (p<0.05) in LVEDD (53.5±6.7 mm; ∆LVEDD of ±7.2 mm), LVEDD/BSA (28.3±3.0 mm/m²), LV end-systolic diameter (LVEDD/BSA) (20.5±0.6 mm/m²), LV diastolic volume (145.5±32.7 ml), LV systolic volume (73.6±25.2 ml), LV mass (233.9±68.8 g); and an increase (p<0.05) in sphericity index (1.57±0.18), and only 5.9 patients (n=1) had final ≥grade II/IV mitral regurgitation.

The initial LVEF of patients who recovered LV function was 24.9±9.0% and was not significantly different (p=0.58) from the 26.5±11.2% of those who did not recover.

Patients with LVRR had lower BNP at the end of follow-up (143.5±137.5 vs. 36.9±34.3 pg/ml, p=0.01) and fewer major cardiac events (death or HF hospitalization) (5.9% vs. 33.3; p=0.03) compared to those who did not have LVRR.

Predictors of left ventricular reverse remodeling

Baseline predictors of LVRR are detailed in Table 2. Patients who recovered LV function were younger (60.6±8.8 vs. 54.7±10.8 years, p=0.04) and had a lower LVEDD/BSA ratio (35.2±4.1 vs. 32.3±4.8 mm/m²), p=0.03) and higher creatinine clearance (94.3±27.3 vs. 121.3±58.2, p=0.03). No association was found between levels of 25(OH)D, CA-125, hs-CRP, Lp(a), noradrenaline, adrenaline, renin or aldosterone and reverse remodeling.

Biomarkers at clinical presentation

Patients who presented at baseline with worse NYHA class (III/IV) had higher levels of CA-125 (21.6±58.1 vs. 116.0±255.3 U/ml), cystatin C (0.76±0.16 vs. 0.92±0.05 mg/l), BNP (257.5±391.0 vs. 968.5±950.1 pg/ml) and hs-CRP (2.6±3.4 vs. 10.9±13.4 mg/l) (p=0.05) (Table 3).

Patients with pulmonary congestion or ankle edema also had higher levels of CA-125, BNP and hs-CRP (p<0.01) (Table 3).

Correlations between biomarkers and with echocardiographic parameters

There was a significant correlation between four biomarkers: CA-125, BNP, hs-CRP and uric acid. BNP also correlated negatively with 25(OH)D (r=-0.43, p<0.05) (Table 4).

We found some correlations between biomarkers and echocardiographic variables (Table 5). BNP correlated directly with LV dimensions (r=0.49), LV volumes (r=0.51), PASP (r=0.43) and measures of diastolic dysfunction (E/E′)
and was inversely correlated with LVEF (r=-0.50) and e′ velocities (r=-0.32) (p<0.05).

CA-125 correlated with LA volume/BSA (r=0.46), E/A ratio (r=0.60) and PASP (r=0.49) (<0.05).

There was a marginal correlation between hs-CRP and LVEF (r=-0.28, p=0.05), and LV diastolic volume/BSA (r=0.32, p=0.05).

Levels of 25(OH)D were only correlated with PASP (r=-0.42) and E/A ratio (r=0.20) (p<0.05).

Discussion

One of the most important areas of biomarker research is the role of biomarker profiling to better characterize the phenotype of patients who might best respond to therapeutic interventions, whether drug or device therapies.10 The newly-defined HF with recovered LVEF represents a distinct HF phenotype with biochemical properties and natural history that differ from the traditional HF population.11 Predictors of LVRR probably distinguish patients in whom LVEF may recover with medical therapy only from patients who may require cardiac devices or more aggressive strategies, including heart transplantation. Patients who have recovered LVEF do not, in theory, have indications for ICD or CRT therapy, thus complicating the timing of implantation of these devices.

Data now suggest that biomarkers may also be useful to predict or monitor LVRR. A new clinical score, the ST2-R2

Our study set out to find predictors of LVRR. In our population, LVRR occurred in one third of DCM patients, who were younger and had better renal function and smaller LVEDD. These results are consistent with other studies. In a large study, LVRR was found in 89 of 242 idiopathic DCM patients (37%) and baseline predictors were higher systolic blood pressure and the absence of LBBB. Binkley et al. showed that patients who recovered LV function were younger, had higher systolic blood pressure, lower serum creatinine level, shorter QRS interval, a lower prevalence of diabetes and history of hypertension, were more frequently female and had a lower prevalence of ischemic cardiomyopathy.

In our population LVRR was also associated with lower BNP at the end of follow-up and with favorable outcome and reduced rate of cardiac events. In a recent study with elderly HF patients, intensified medical therapy led to improvement in LVEF and to reverse remodeling. NT-proBNP guided therapy was associated with a greater improvement in LVEF than symptom-guided therapy in both patients aged 60 to 74 and in those aged ≥75 years.

We found no association between BNP, 25(OH)D, CA-125, hs-CRP or Lp(a) and LV reverse remodeling. As expected, patients with poorer functional class, pulmonary congestion, or ankle edema had higher BNP levels. Atrial natriuretic peptide and BNP are produced in response to myocardial stretch due to pressure or volume overload. In the ICON study, increasing severity of HF, as measured by NYHA functional class and symptom severity, correlated directly with increasing BNP concentrations. In our study, BNP also correlated with LV dimensions, LV volumes, LVEF, PASP and measures of diastolic dysfunction (E/e' and e' velocities). Since BNP is primarily synthesized by cardiomyocytes, it is not surprising that the highest levels are secreted by the LV. Studies have demonstrated that BNP and NT-proBNP levels correlate positively with LV dimensions, volumes, and mass and are inversely related to LVEF; the strongest correlations have been reported for BNP with LV diastolic wall stress consistent with stretch-mediated BNP secretion. BNP levels increase with greater severity.
of overall diastolic dysfunction, correlating with indices of filling pressure as well as with indices of compliance and myocardial relaxation.\textsuperscript{20,21}

Serum CA-125, a high molecular weight glycoprotein, is a tumor marker widely used in patients with ovarian cancer.\textsuperscript{22} Recently, increased serum CA-125 levels, in parallel with catecholamines and natriuretic peptides, have also been documented in patients with HF.\textsuperscript{23} However, little is known about the biologic role of this substance: whether it simply reflects increased activation of the cytokine pathway or is an active substance actually responsible for myocardial and/or peripheral dysfunction. In our population, CA-125 was not a predictor of LVRR, but did predict more severe presentation as shown by worse functional class and pulmonary and peripheral congestion. It also correlated with measures of diastolic dysfunction (LA volume, E/A ratio and PASP), as well as with BNP levels, hs-CRP and uric acid, suggesting a potential pathogenic link between inflammatory activation and this marker of systemic congestion. Kouris et al. showed that patients in NYHA classes III and IV had significantly higher mean CA-125 values than patients in class II; serum CA125 levels correlated weakly with PASP and renal function.\textsuperscript{24} A study analyzing CA-125 levels and LV dysfunction in patients on hemodialysis showed they were positively correlated with pro-BNP and C-reactive protein (CRP) levels, as well as with LVEDD, LVESD and LV mass index.\textsuperscript{25}

CRP is a plasma protein that participates in the systemic response to inflammation, an important mechanism in the progression of HF. A landmark review showed that CRP concentrations were higher than normal in 70% of HF patients, and were directly related to severity of HF.\textsuperscript{26} In a recent study of patients with acute HF, both hs-CRP and NT-proBNP were independent predictors of 12-month mortality.\textsuperscript{27} In our patients, hs-CRP was associated with clinical severity and marginally correlated with measures of systolic dysfunction (LVEF and LVEDV/BSA). In a previous study, CRP levels increased in parallel with NYHA class and were also related to higher readmission and mortality rates.\textsuperscript{28}

Functional vitamin D receptors are present in cardiac cells and their activation affects gene expression, proliferation and contraction of cardiomyocytes. Vitamin D may thus contribute to the development of cardiac hypertrophy and fibrosis.\textsuperscript{29} In our population, 25(OH)D was not a predictor of LVRR and was only correlated with PASP and E/A. In a study of subjects with HF, LVEDD, LVESD, LVEDV and LVESV were significantly larger and fractional shortening was lower in patients with 25(OH)D <25 nmol/l than with 25(OH)D ≥25 nmol/l (p<0.05); log values of 25(OH)D were negatively correlated with LVEDD and LVEDV (r=-0.28; p<0.05).\textsuperscript{30}

In a recent study of ambulatory patients with chronic HF, Ky et al.\textsuperscript{30} tested the hypothesis that a group of seven biomarkers (BNP, soluble fms-like tyrosine kinase receptor, hs-CRP, ST2, cardiac troponin I, uric acid and creatinine) could be combined into a multimarker score that would predict risk of adverse outcome, defined as death, cardiac transplantation or ventricular assist device placement. Patients in the highest tertile of the multimarker score had a 13.7-fold increased risk of adverse outcomes compared with the lowest tertile.

The approximate cost per patient of the biomarkers that we used is currently around €100. In-hospital care is responsible for ~60% of HF-related costs and median hospitalization cost is €9475,\textsuperscript{1} but in many cases costs are much higher due to frequent comorbidities and need for intensive care. If the use of biomarkers succeeds in preventing just one hospitalization, this could be a highly cost-effective strategy.

**Study limitations**

In our center, high-sensitivity troponin I has only been available since last year, so measurements at initial assessment are not available. However, plasma samples have been frozen in liquid nitrogen and a study with emerging biomarkers is ongoing. Due to the small population it was not possible to perform a multimarker score.

**Conclusions**

In our population, LVRR occurred in one third of DCM patients, especially in younger patients, with better renal function and smaller LVEDD. We can postulate that patients with long-standing disease and larger LV diameters may not recover LV function. CA125, BNP and hs-CRP were predictors of clinical severity but not of reverse remodeling. BNP correlated with parameters of systolic and diastolic dysfunction, while CA-125 correlated with measures of diastolic dysfunction.
